Optimal Macroprudential Policy*

Ko Munakata†, Koji Nakamura‡ and Yuki Teranishi§

Abstract

We introduce the financial market friction through the search and matching in the loan market into a standard New Keynesian model. We reveal that the second order approximation of social welfare includes the terms relating credit, such as credit market tightness, the volume of credit, and a loan separation rate, in addition to the inflation rate and the consumption under the financial market friction. Our analytical result justifies the reason why the optimal policy should take the credit variation into account. We introduce a monetary policy and macroprudential policy measures for the financial stability into the model. The optimal outcome is achieved through the monetary and macroprudential policies by taking into account not only price stability but also financial stability.

JEL Classification: E44; E52; E61

Keywords: Optimal macroprudential policy; optimal monetary policy; financial market friction

1 Introduction

Financial crises reveal critical roles of financial markets by inducing real economic disruptions. Under such a situation, accompanied with a lack of room of the monetary policy, policy makers shed light on the policy measures including macroprudential policy for financial stability as a new frontier of the macro policy.

Some empirical and theoretical studies clarify the need of policy measures for financial stability. Borio (2011) empirically shows a difference between financial cycles and business cycles and then justifies necessity of coexistence of the monetary policy and the macroprudential policy. Quantitative studies for optimal policy under well-known models with financial frictions have started to be conducted. For example, Quint and Rabanal (2011) assume the DSGE model with real, nominal and financial frictions, and study the optimal combination of the monetary and macroprudential policies. They show that a social welfare improves when the policy maker’s objective function includes the credit term, implying that the macroprudential policies are quantitatively important. Similar approach is taken by Suh (2012) and Kannan, Rabanal, and Scott (2012) under some difference in DSGE models. Suh (2012) shows that the macroprudential policy should respond to credit to improve a social welfare apart from the monetary policy responses to the output gap and the inflation rate. Kannan, Rabanal, and Scott (2012) show that the monetary policy reaction to credit growth can help macroeconomic stabilization. These positive analyses, however, do not provide the answers for why counting the credit into the policy can improve welfare.

In this paper, we aim to reveal a criteria for optimal policy under a financial market friction. Our focus is on a normative analysis rather than a positive analysis. To introduce a financial friction into a standard New Keynesian model, we assume search and matching in the loan market, following Wasmer and Weil (2000) and Den Haan, Ramey, and Watson (2003). Based on the model, we approximate the consumer’s welfare function in the

---

1 Drehmann, Borio, and Tsatsaronis (2012) also show such empirical results.

2 Blanchflower and Oswald (1998) and Peterson and Rajan (2002) empirically show that search and matching frictions play an important role in the loan market.

3 This type of search and matching friction is also assumed in the labor market as in Mortensen and Pissarides (1994) and Rogerson, Shimer, and Wright (2005). Ravenna and Walsh (2011) derive the quadratic welfare function in the model with the search and matching friction in the labor market.

4 Different types of financial frictions are assumed in other former studies. Bernanke, Gertler, and Gilchrist (1999, henceforth BGG), which is the first to stress that credit market imperfections have a signifi-
second order and reveal the property of the optimal policy for financial stability. A new finding is that approximated welfare function includes a term closely related to the volume of credit in addition to the inflation rate and consumption. This result theoretically justifies necessity of financial stability for optimal policy. Then, we introduce a monetary policy and macroprudential policy. The macroprudential policy aims to achieve financial stability. We show that optimal policy outcomes change according to the type of macroprudential policies. When the degree of competition in the loan market through Nash bargaining is endogenized and the macroprudential policy, which is interpreted as a type of a financial regulation policy, intervenes in such a competition, the optimal macroprudential policy perfectly stabilizes the inflation rate to a cost-push shock accompanied with the monetary policy. This is because the macroprudential policy contributes to price stability through the cost channel. When a macroprudential policy intervenes in a endogenous credit separation, this macroprudential policy can be interpreted as a total lending control. In this case, a welfare function additionally includes terms for credit separation and the optimal macroprudential policy adjusts the separation rate by taking into account trade-off among the separation rate, credit market tightness, the inflation rate, and consumption. In any case, the macroprudential policy for financial stability have a close relation with price stability and consequently with the monetary policy.

The rest of the paper is organized as follows. The following section sets up a model. In Section 3, we derive the second order approximation from the consumer’s utility function and comment on its properties. In Section 4, we show the linearized system of the model. In Section 5, we derive an optimal monetary policy and show the properties of this optimal monetary policy. In Section 6, we derive optimal macroprudential policy for financial stability under various settings and reveal the interaction between the optimal macroprudential and the optimal monetary policy. In Section 7, we conclude the paper.

---

In the BGG model, this financial market wedge is determined by time-varying leverage, in that endogenous mechanisms in credit markets work to amplify and propagate shocks to the economy. In Bianchi (2010), the financial market friction is introduced by externalities in which private agents undervalue the dynamics of net worth since the agents fail to internalize spillover effect among them.
2 The Model

2.1 Household

A representative household in our model enters the goods market to consume $C_t$ in real terms with price $P_t$, and receives $\Pi_t$ as a lump-sum profit from wholesale firms and a bank in real terms. In addition, the household deposits $D_t$ in its bank account at the beginning of time $t$, and receives the deposit back with the nominal interest rate $R^D_t$ at the end of time $t$.

Assuming that the utility of the household depends only on the consumption $C_t$, the household’s problem is expressed as

$$\max_{C,D} \mathbb{E}_t \sum_{i=0}^{\infty} \beta^i u(C_{t+i}),$$

subject to the budget constraint

$$C_t = \Pi_t + \frac{R^D_{t-1} D_{t-1} - D_t}{P_t}.$$ 

We assume the following utility function.

$$u(C_t) = \frac{C_t^{1-\sigma}}{1-\sigma},$$

where $\sigma$ is a coefficient of relative risk aversion of the household.

This optimization problem leads to

$$\lambda_t = C_t^{-\sigma},$$

$$1 = \beta \mathbb{E}_t \frac{\lambda_{t+1}}{\lambda_t} \frac{P_t}{P_{t+1}} R^D_t,$$

where $\lambda_t$ is the Lagrangian multiplier in the household’s optimization problem.

It is assumed that the consumption $C_t$ consists of goods labeled by $j \in [0,1]$. The consumption of each good $c_t(j)$ is related to the total consumption $C_t$ by

$$C_t = \left[ \int_0^1 c_t(j) d\xi \right]^{\xi_t},$$

where $\xi_t \in (1,\infty)$ is an exogenous stochastic variable related to the elasticity of substitution. The households choose the level of consumption of each good $c_t(j)$ in order to
minimize the cost \( f_0^1 p_t(j) c_t(j) dj \), given the level of total consumption \( C_t \) and the price of each good \( p_t(j) \). This minimization yields

\[
c_t(j) = \left[ \frac{p_t(j)}{P_t} \right]^{-\varepsilon_t} C_t,
\]

where

\[
P_t \equiv \left[ \int_0^1 p_t(j)^{1-\varepsilon_t} dj \right]^{1/(1-\varepsilon_t)}.
\]

### 2.2 Wholesale Firms

Each firm seeks for a credit line in the credit market at time \( t \) if the firm is a credit seeker. The number of credit seekers is \( u_t \), the total number of credit lines is \( L_t \), and the amount of each credit line in real terms is \( a \). If a firm has a credit contract at time \( t - 1 \) but fails to receive an update on the credit line with the probability \( \rho \) at time \( t \), the firm becomes a credit seeker. On the other hand, if a firm does not have a credit contract at time \( t - 1 \), it automatically becomes a credit seeker at time \( t \). Under this setting, the number of credit seekers at time \( t \) is obtained by

\[
u_t = 1 - (1 - \rho)L_{t-1}.
\]

Credit seeking firms participate in the bargaining of credit lines with a representative bank. As a result of the matching process, \( L_t \) (the number of credit lines at time \( t \)) is related to \( L_{t-1} \) by

\[
L_t = (1 - \rho)L_{t-1} + p_t^FU_t,
\]

where \( p_t^F \) is the probability of getting a credit line for each credit seeking firm.

When a firm has a credit line, the firm uses the amount of credit \( a \) to buy retail goods \( a(j) \), which are then used as an input or a sweat cost to produce wholesale goods with productivity \( Z \). A firm’s gain when it has a credit line is then

\[
f_0^1 = \frac{Z}{\mu_t} - aR_t^L + \beta E_t \left[ \frac{\lambda_{t+1}}{\lambda_t} \right] \left[ (1 - \rho)f_t^1 + \rho(p_t^F f_t^1 + (1 - p_t^F)f_{t+1}^0) \right],
\]

where \( R_t^L - 1 \) is the real interest rate for the credit, \( \mu_t \equiv \frac{P_t}{P_t^w} \) is the price markup by retail firms, and \( P_t^w \) is the price of a wholesale good. The first two terms show the net profit
from production at time $t$ and the third term is the discounted present value of the future profit. On the other hand, a firm’s gain when it fails to receive a credit line is

$$f_t^0 = \beta E_t \frac{\lambda_{t+1}}{\lambda_t} [p_{t+1} f_{t+1}^F + (1 - p_{t+1}) f_{t+1}^F].$$

Since the firm cannot obtain a credit line, it does not produce at time $t$ and it only has the discounted future values. These equations imply that the gain from a credit line for a credit seeking firm is

$$f_t \equiv f_t^1 - f_t^0 = \frac{Z}{\mu_t} - a R_t^F + \beta E_t \frac{\lambda_{t+1}}{\lambda_t} (1 - \rho) (1 - p_{t+1}) f_{t+1}.$$  \tag{5}

### 2.3 Bank

A representative bank decides on the number of credit vacancies $v_t$ to post in order to maximize its profit $B_t$ with respect to $L_t$

$$B_t = (R_t^L - 1) a L_t - \frac{(R_t^D - 1) D_t}{P_t} - \kappa v_t + \beta E_t \frac{\lambda_{t+1}}{\lambda_t} B_{t+1},$$

subject to

$$L_t = (1 - \rho) L_{t-1} + q^B v_t,$$

where $\kappa$ is a cost for posting each credit vacancy and $q^B$ is the vacancy filling rate. In reality, $\kappa$ includes the cost of collecting borrowers’ information and examining the loan applications. This maximization problem yields

$$\frac{\kappa}{q^B} = (R_t^L - 1) a + \beta E_t \frac{\lambda_{t+1}}{\lambda_t} (1 - \rho) \frac{\kappa}{q^B}. \tag{6}$$

The bank’s expected gain from one credit line should be, with free entry, the same as the cost of a vacancy post. This condition implies that the bank’s gain for a credit line is

$$J_t = \frac{\kappa}{q^B}. \tag{7}$$

We assume that the cost of posting credit vacancies $\kappa v_t$ is again paid by consumption of retail goods $v_t(j)$, in a similar way as the household consumption $C_t$ and the firms’ input for production $a$. Therefore, the demand for good $j$ and the total demand are given by

$$y_t^d(j) \equiv c_t(j) + a(j) L_t + \kappa v_t(j),$$

$$y_t^s \equiv \sum_j y_t^d(j).$$
and

\[ Y_t^d \equiv C_t + aL_t + \kappa v_t, \]

respectively, where

\[ y_t^d(j) = \left[ \frac{P_t(j)}{P_t} \right]^{-\epsilon_t} Y_t^d. \]  

(8)

2.4 Retail Firms

A retail firm producing goods \( j \) faces the demand given by the equation (8), and it has to pay \( P_{wt} \) to buy wholesale goods as an input to produce the final goods. In order to introduce the price stickiness, it is assumed that a firm can adjust its price each period with probability \( 1 - \omega \) as in the model by Calvo (1983). The profit maximization problem of a retail firm when it has a chance to adjust its price \( P_t^* \) becomes

\[
\max_{P_t} \sum_{i=0}^{\infty} (\omega/\beta)^i E_t \left[ \left( \frac{\lambda_{t+i}}{\lambda_t} \right) \left( \frac{(1 + \tau)(P_t^* - P_{1+i}^w)}{P_{1+i}} \right) \left( \frac{P_t^*}{P_t} \right)^{-\epsilon_{t+i}} Y_{t+i}^d \right],
\]

where the demand equation (8) is used. We here assume that the subsidy for firms \( \tau \) is set to ensure that the price flexibility is achieved at the efficient steady-state equilibrium discussed below. Note that the average price level \( P_t \) is given by

\[ P_t^{1-\epsilon_t} = (1 - \omega)(P_t^*)^{1-\epsilon_t} + \omega P_{t-1}^{1-\epsilon_t}. \]

2.5 Loan Market Matching

The number of new credit matches is

\[ p_t^F u_t = q_t^B v_t = \chi u_t^{1-\alpha} v_t^\alpha, \]

in a Cob-Douglas form where \( \alpha (0 < \alpha < 1) \) is a substitution for \( u_t \) and \( v_t \), and \( \chi \) is a constant parameter for matching. To make the calculation clearer, we use the credit market tightness

\[ \theta_t = \frac{v_t}{u_t}, \]

(9)

so that
In the loan market, the total gain from loan extension is the sum of credit seeking firms’ gain $f_t$ and the bank’s gain $J_t$ as follows

$$
(1 - b)f_t = bJ_t.
$$

For convenience, we simplify the equations (5) and (6) by using the equations (10), (11), (13), and (7) to eliminate $p_t^F$, $q_t^B$, $f_t$, and $J_t$, yielding

$$
\frac{b}{1 - b} \frac{\kappa}{\lambda_t} \theta_t^{1-a} = \frac{Z}{\mu_t} - aR_t^L + \beta E_t \frac{\lambda_t}{\lambda_t} \frac{\lambda_t+1}{\lambda_t} (1 - \rho) \left(1 - \chi \theta_t^{\alpha+1}\right) \frac{b}{1 - b} \frac{\kappa}{\lambda_t+1} \theta_t^{1-a}
$$

and

$$
\frac{\kappa}{\lambda_t} \theta_t^{1-a} = (R_t^L - 1)a + \beta E_t \frac{\lambda_t+1}{\lambda_t} (1 - \rho) \frac{\kappa}{\lambda_t+1} \theta_t^{1-a},
$$

respectively. If we further eliminate $R_t^L$ from these equations, we obtain the following condition that relates to the markup $\mu_t$ to the credit market tightness $\theta_t$:

$$
\frac{Z}{\mu_t} = a + \frac{1}{1 - b} \frac{\kappa}{\lambda_t} \theta_t^{1-a} - \beta E_t \frac{\lambda_t+1}{\lambda_t} (1 - \rho) \frac{1}{1 - b} \left(\frac{\kappa}{\lambda_t+1} \theta_t^{1-a} - b\theta_t+1\right).
$$
2.6 Market Clearing Condition

Since one unit of the wholesale goods is needed as an input to produce one unit of each retail goods \( j \), the market clearing condition for the wholesale goods is

\[
ZL_t = \int_0^1 y^d_t(j) dj.
\]

Together with the demand equation for the retail goods (8), the following market clearing condition is obtained:

\[
\frac{ZL_t}{Q_t} = C_t + aL_t + \kappa v_t. 
\tag{15}
\]

where

\[
Q_t = \int_0^1 \left[ \frac{P_t(j)}{P_2} \right]^{-\varepsilon_t} dj
\tag{16}
\]

represents the dispersion of the prices of retail goods due to the price stickiness for retail firms.

3 Welfare Criteria

3.1 Efficient Steady-State Equilibrium

The second order expansion of the household’s utility function is set around the efficient steady-state equilibrium, which is the equilibrium designed by a social planner without credit matching inefficiency or price dispersion. Such a situation can only be achieved (1) when the Hosios condition \( b = 1 - \alpha \) for the bargaining power of firm \( b \) and the matching share \( \alpha \) is satisfied and (2) when the subsidy for retail firms \( \tau \) is chosen to make sure

\[
\tilde{\tau} = \frac{\tau}{(\tau-1)(1+\tau)} = 1. 
\]

Under these assumptions, the optimization problem for the social planner is expressed as

\[
\max_{C,L,u,\theta} \sum_{t=0}^{\infty} \beta^t \left\{ \frac{C^1_{t+i}}{1-\sigma} + \lambda_{t+i} [ZL_{t+i} - aL_{t+i} - \kappa u_{t+i} - C_{t+i}] 
+ \psi_{t+i} [(1 - \rho)L_{t+i-1} + \chi \theta_{t+i} - L_{t+i}] + s_{t+i} [u_{t+i} - 1 + (1 - \rho)L_{t+i-1}] \right\},
\]

where \( \lambda_t, \psi_t, \) and \( s_t \) are Lagrangian multipliers for the constraints.
The solution to this optimization problem yields the following condition for the efficient steady-state equilibrium:

\[ Z - a - \frac{\kappa \pi}{\alpha \rho L} = -\beta (1 - \rho) \frac{\kappa \pi}{\alpha \rho L} \left( 1 - (1 - \alpha) \frac{\rho L}{\pi} \right), \]

which is simplified for convenience as

\[ \delta_1 = -\beta \delta_2. \]  

(17)

Note that the bar above each variable (e.g., \( \pi \)) implies the efficient steady-state value of the variable \( (\pi_t) \).

### 3.2 Policy Objective Function

The second order expansion of the household’s utility function around the efficient steady state yields

\[ u(C_t) \approx u(C) + u_c C \left( \hat{\pi}_t + \frac{1}{2} \hat{\pi}^2_t \right) - \frac{1}{2} \sigma u_c C \hat{\pi}^2_t, \]

where \( \hat{\pi}_t \) is the log-deviation of \( C_t \) from the efficient steady-state value \( C \). The goal of the following calculation in this subsection is to express this utility \( u(C_t) \) by only \( \hat{l}_t, \hat{l}_{t-1} \), and the inflation rate \( \pi_t \equiv \hat{\pi}_t - \hat{\pi}_{t-1} \). This calculation closely follows the derivation of a policy objective function by Ravenna and Walsh (2011) for the search and matching in the labor market. By using the market clearing condition of the equation (15),

\[ \hat{\pi}_t + \frac{1}{2} \hat{\pi}^2_t = -\frac{Z \hat{l}_t}{C} \hat{\pi}_t + \frac{Z - a}{C} \left( \hat{l}_t + \frac{1}{2} \hat{\pi}^2_t \right) - \frac{\kappa \pi}{C} \left( \hat{\pi}_t + \frac{1}{2} \hat{\pi}^2_t \right). \]  

(18)

Note that the efficient steady-state value of the price dispersion term \( Q_t \) is \( Q = 1 \), and the log-deviation of this term \( \hat{\pi}_t \) is already in the second order, as is shown below.

Using the equation (9)

\[ \hat{\pi}_t = \hat{\pi}_t + \hat{\pi}_t, \]

and the equation (4)

\[ \hat{\pi}_t + \frac{1}{2} \hat{\pi}^2_t = -\eta \left( \hat{l}_{t-1} + \frac{1}{2} \hat{\pi}^2_{t-1} \right), \]

where

\[ \eta \equiv (1 - \rho) \frac{\sigma}{\pi}, \]
Then, we obtain up to the second order

\[ \hat{t}_t + \frac{1}{2} \hat{\theta}_t^2 = \left( \hat{t}_{t-1} + \frac{1}{2} \hat{\theta}_{t-1}^2 \right) - \eta \left( \hat{t}_{t-1} + \frac{1}{2} \hat{\theta}_{t-1}^2 \right) - \eta \hat{\theta}_{t-1}. \]  

By using this equation and the equation (12), we can eliminate \( \hat{\theta}_t \) and get

\[ u(C_t) = u(C_t) - u_c Z \tilde{q}_t + u_c C \left[ \frac{L}{C} \left( \delta_1 \hat{t}_t + \delta_2 \hat{t}_{t-1} \right) + \frac{L}{2C} \left( \delta_1 \hat{\theta}_t^2 + \delta_2 \hat{\theta}_{t-1}^2 \right) - \frac{\kappa \eta}{2(\alpha \rho)^2} \left( \hat{t}_t - \rho_u \hat{t}_{t-1} \right)^2 \right] \]

\[ - \frac{1}{2} \alpha u_c C \left( \frac{L}{C} \right)^2 \left( \delta_1 \hat{\theta}_t + \delta_2 \hat{\theta}_{t-1} \right)^2, \]

where \( \rho_u \equiv 1 - \rho - \eta \).

Thus, the utility of the equation (1) is rewritten as

\[ \sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = \frac{u(C_t)}{1 - \beta} - u_c Z \sum_{i=0}^{\infty} \beta^i \hat{q}_{t+i} \]

\[ + u_c L \sum_{i=0}^{\infty} \beta^i \left( \delta_1 \hat{t}_{t+i} + \delta_2 \hat{t}_{t+i-1} \right) \]

\[ + \frac{1}{2} u_c L \sum_{i=0}^{\infty} \beta^i \left( \delta_1 \hat{\theta}_{t+i}^2 + \delta_2 \hat{\theta}_{t+i-1}^2 \right) \]

\[ - u_c \kappa \eta \frac{1 - \alpha}{2(\alpha \rho)^2} \sum_{i=0}^{\infty} \beta^i \left( \hat{t}_{t+i} - \rho_u \hat{t}_{t+i-1} \right)^2 \]

\[ - \frac{1}{2} \sigma u_c C \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left( \delta_1 \hat{\theta}_{t+i} + \delta_2 \hat{\theta}_{t+i-1} \right)^2. \]

By using the efficient steady-state condition given by the equation (17), the two terms on the right-hand side of the equation above are shown to depend only on \( \hat{t}_{t-1} \), and the utility becomes

\[ \sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = -u_c Z \sum_{i=0}^{\infty} \beta^i \hat{q}_{t+i} \]

\[ - u_c \kappa \eta \frac{1 - \alpha}{2(\alpha \rho)^2} \sum_{i=0}^{\infty} \beta^i \left( \hat{t}_{t+i} - \rho_u \hat{t}_{t+i-1} \right)^2 \]

\[ - \frac{1}{2} \sigma u_c C \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \hat{t}_{t+i} + \hat{t}_{t+i-1} \right)^2 \]

\[ + t.i.p., \]
where \( t.i.p. \) denotes "terms independent of policy."

Next, we consider the sum over the price dispersion terms \( \hat{q}_{t+i} \). By the definition of the equation (16),

\[
\hat{q}_t = \int_0^1 dj \exp \left[ -\varepsilon_t (\hat{p}_t(j) - \hat{p}_t) \right] - 1
\]

\[
\simeq -\varepsilon (\Delta_t^F - \hat{p}_t)(1 + \bar{\varepsilon}_t) + \frac{1}{2} \varepsilon^2 \left[ \Delta_t^V + (\Delta_t^F - \hat{p}_t)^2 \right],
\]

where \( \Delta_t^F \equiv E_j \hat{p}_t(j) = \int_0^1 \hat{p}_t(j) dj \) and \( \Delta_t^V \equiv Var_j \hat{p}_t(j) = E_j \hat{p}_t(j)^2 - (E_j \hat{p}_t(j))^2 \). Since the definition of the aggregate price \( P_t \) given by the equation (3) can be used to show that

\[
\Delta_t^F - \hat{p}_t \simeq -\frac{1}{2} (1 - \varepsilon) \Delta_t^V.
\]

Up to the second order in \( \hat{p}_t \), we can thus rewrite \( \hat{q}_t \) as

\[
\hat{q}_t \simeq \frac{1}{2} \varepsilon \Delta_t^V,
\]

leading to

\[
\sum_{i=0}^\infty \beta^i \hat{q}_{t+i} = \frac{1}{2} \varepsilon \sum_{i=0}^\infty \beta^i \Delta_{t+i}^V.
\]

On the other hand, the equation to obtain \( \Delta_t^V \) is written as

\[
\Delta_t^V = Var_j \hat{p}_t(j)
\]

\[
= E_j (\hat{p}_t(j) - \Delta_{t-1}^E)^2 - (\Delta_t^E - \Delta_{t-1}^E)^2.
\]

Here, we remember that only the fraction \( 1 - \omega \) of all firms adjust their prices to \( P_t^* \), while other firms do not change their prices \( p_{t-1}(j) \), \( \hat{p}_t \), the log-deviation of \( P_t^* \), can in turn be expressed by \( \hat{p}_t \) and \( \hat{p}_{t-1} \). Hence,

\[
\Delta_t^V \simeq \omega \Delta_{t-1}^V + (1 - \omega) E_j \left( \frac{1}{1 - \omega} \hat{p}_t - \frac{\omega}{1 - \omega} \hat{p}_{t-1} - \hat{p}_{t-1} \right)^2 - (\hat{p}_t - \hat{p}_{t-1})^2,
\]

up to the second order again in \( \hat{p}_t \). Using the inflation rate \( \pi_t \equiv \hat{p}_t - \hat{p}_{t-1} \), we thus have

\[
\Delta_t^V \simeq \omega \Delta_{t-1}^V + \frac{\omega}{1 - \omega} \pi_t^2.
\]
The sum of $\Delta_t^V$ becomes

$$
\sum_{i=0}^{\infty} \beta^i \Delta_{t+i}^V = \Delta_t^V + \omega \beta \sum_{i=0}^{\infty} \beta^i \Delta_{t+i}^V + \frac{\omega \beta}{1 - \omega} \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2.
$$

We therefore obtain

$$
\sum_{i=0}^{\infty} \beta^i \Delta_{t+i} = \frac{\omega \beta}{(1 - \omega)(1 - \omega \beta)} \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2 + \text{t.i.p.},
$$

Combining this equation with the equations (20) and (21),

$$
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = -\frac{1}{2} u_c Z T^\frac{\varepsilon}{\delta} \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2
\quad - u_c \kappa \sigma \frac{1 - \alpha}{2(\alpha \rho)^2} \sum_{i=0}^{\infty} \beta^i \left( \hat{u}_{t+i} - \rho_u \hat{u}_{t+i-1} \right)^2
\quad - \frac{1}{2} \sigma u_c \tilde{C} \left( \frac{T}{C} \tilde{z}_2 \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \hat{u}_{t+i} + \hat{u}_{t+i-1} \right)^2
\quad + \text{t.i.p.},
$$

where

$$\delta \equiv \frac{(1 - \omega)(1 - \omega \beta)}{\omega}.
$$

We also use the approximations up to the second order

$$
\hat{\theta}^2_{t+i} = \frac{1}{(\alpha \rho)^2} \left( \hat{u}_{t+i} - \rho_u \hat{u}_{t+i-1} \right)^2 = \frac{1}{(\alpha \rho \eta)^2} \left( \hat{u}_{t+i} - \rho_u \hat{u}_{t+i-1} \right)^2,
$$

and

$$
\tilde{c}_{t+i}^2 = \left( \frac{T}{C} \tilde{z}_2 \right)^2 \left( -\beta \hat{u}_{t+i} + \hat{u}_{t+i-1} \right)^2,
$$

and finally, we have the following second order expansion of the household’s utility function

$$
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = -\frac{1}{2} \sum_{i=0}^{\infty} \beta^i \left( \lambda \pi_{t+i}^2 + \lambda \hat{\theta}^2_{t+i} + \lambda \tilde{c}_{t+i}^2 \right) + \text{t.i.p.},
$$

where $\lambda \equiv u_c Z T^\frac{\varepsilon}{\delta}$, $\lambda_\theta \equiv u_c \kappa \sigma (1 - \alpha)$ and $\lambda_c \equiv \sigma u_c \tilde{C}$.

We note that, even if we introduce exogenous productivity shock $Z_t$ in the model, we can derive a mathematically-similar formula for the utility by taking the difference from the efficient stochastic state. This point is discussed in the appendix.
The optimal policy faces the trade-off among the inflation rate, consumption, and credit market tightness. The credit market tightness is a new feature for the optimal policy under the loan market friction. Moreover, the approximated welfare function can be transformed as

\[
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = - \sum_{i=0}^{\infty} \beta^i \frac{1}{2} \left[ \lambda_\pi \pi^2_{t+i} + \lambda_\theta \frac{\rho_\theta}{\alpha} \left( \tilde{\theta}_{t+i} - \rho_\theta \tilde{\theta}_{t+i-1} \right)^2 + \lambda_c \tilde{c}_{t+i}^2 \right].
\]

Thus, the optimal policy should respond to the changes in credit. This result theoretically supports the papers of Quint and Rabanal (2011), Suh (2012), and Kannan, Rabanal, and Scott (2012), claiming in numerical simulations that the policy should respond to the changes in credit, in addition to the inflation rate and the output gap.

### 3.3 Analysis for Welfare Criteria

In this section, we analyze the dependence of the welfare function on different parameters, especially focusing on the weight of the term corresponding to the financial friction.

To start the analysis, we fix the parameter values as shown in Table 1. We assume that each period corresponds to one quarter, and set the discount factor \( \beta = 0.99 \) and the probability of the price adjustment for retail firms as \( 1 - \omega = 0.2 \). As for the other parameters, since our objective is not to calibrate the model but to illustrate the important characteristics of the financial frictions in our model, the set of the parameter values in Table 1 is to be taken as just one example, and it is confirmed that the qualitative conclusion in this section apply to a wide range of parameter values.

As shown in Figure 1, as the cost for posting each credit vacancy \( \kappa \) increases, the relative weight for credit to that for the consumption in the approximated welfare function \( (\lambda_\theta / \lambda_c \text{ of the equation (22)}) \) increases. This is because the wedge of the financial market friction increases when \( \kappa \) increases since, as shown in the equation (15), it is related with the resource of economy used to match the loan \( \kappa \tilde{\theta} \).

The same result holds for \( \rho \), the probability of failing to receive an update on the credit line. When \( \rho \) increases, \( \lambda_\theta / \lambda_c \) increases as shown in Figure 2. This is also because the

---

5 The other parameters adopted in the Figure 1 are given by Table 1. Note that, when the cost for posting each credit vacancy \( \kappa \) changes, the steady-state values of the variables \( \pi \) and \( \tilde{C} \) shifts to satisfy the efficient steady-state equilibrium condition as shown in the equation (17).

6 The other parameters adopted in the Figure 2 are given by Table 1. Note that the variation of \( \rho \) also
increase of $\rho$ raises the cost of holding the credit.

These results imply that the relative weight for the credit term increases when the degree of inefficiency to hold credit increases. In other words, as the degree of market imperfection increases, the optimal monetary policy should take a credit market condition into account more seriously.

4 Linearization

We show the closed linearized system of the economy around the efficient equilibrium. For general stochastic non-efficient state, the Calvo-type stickiness introduced in the retail sector leads to the standard Phillips curve with a cost-push shock $\tilde{z}_t$ as

$$\pi_t = \beta E_t \pi_{t+1} - \delta \left( \frac{1}{e-1} \tilde{z}_t + \tilde{\mu}_t \right).$$

The retail price markup term $\tilde{\mu}_t$ in this equation can be obtained by the linearized equation (14),

$$Z \tilde{\mu}_t = -(1 - \alpha) \frac{\kappa \pi}{\alpha \rho L} \left( \tilde{\theta}_t - \beta \rho_a E_t \tilde{\theta}_{t+1} \right)$$

$$- \beta d_2 \sigma (E_t \tilde{c}_{t+1} - \tilde{c}_t).$$

The IS relation is given by

$$\tilde{c}_t = E_t \tilde{c}_{t+1} - \frac{1}{\sigma} \left( \tilde{r}^D_t - E_t \pi_{t+1} \right).$$

We call $\tilde{c}_t$ as the output gap.

The credit market tightness is given by

$$\tilde{\theta}_t = \frac{\left( \tilde{r}_t - \rho_a \tilde{r}_{t-1} \right)}{\alpha \rho}.$$

The relation between consumption and credit is given by

$$\hat{c}_t = \frac{T \delta_2}{\hat{C}} \left( -\beta \hat{s}_t + \hat{s}_{t-1} \right).$$

affects the steady-state values of the variables $\pi$ and $\hat{c}$.
It is also noteworthy that the log-linearized deviation of the loan interest rate $\hat{r}_t$ is related to the credit market tightness $\hat{\theta}_t$ and the deposit interest rate $\hat{r}_t^D$ by the following equation:

$$aR^L \hat{r}_t^L = (1 - \alpha)\frac{K}{\chi} \hat{\theta}_t^{1-\alpha} - (1 - \rho)\beta(1 - \alpha)\frac{K}{\chi} \hat{\theta}_t^{1-\alpha} E_t \hat{\theta}_{t+1} + (1 - \rho)\beta \frac{K}{\chi} \hat{\theta}_t^{1-\alpha} (\hat{r}_t^D - E_t \pi_{t+1}) .$$

The credit market tightness and the real deposit rate determine the loan interest rate. This equation can be transformed as

$$aR^L \hat{r}_t^L = -\beta(1 - \rho) \frac{\kappa}{\chi} \left[ \frac{(1 - \alpha)}{\alpha \rho} + \beta \frac{T \delta_2}{C} \right] E_t \hat{\theta}_{t+1} + \frac{\kappa}{\chi} \left[ \frac{(1 - \alpha)}{\alpha \rho} + \frac{(1 - \rho)\beta(1 - \alpha)\rho_u}{\alpha \rho} + \frac{(1 - \rho)\beta \sigma T \delta_2 (1 + \beta)}{C} \right] \hat{l}_t + \frac{\kappa}{\chi} \left[ \frac{(1 - \alpha)\rho_u}{\alpha \rho} + \frac{(1 - \rho)\beta \sigma T \delta_2}{C} \right] \hat{l}_{t-1} .$$

Thus, the loan interest rate and credit have a close relation. By using the equation (28), it is possible to include the loan rate term in the approximated welfare function. This result is consistent with ones in Teranishi (2008) and Cúrdia and Woodford (2009). Teranishi (2008) shows that under the staggered cost channel model an approximated welfare function includes the growth of the loan interest rate. Cúrdia and Woodford (2009) show that an approximated welfare function includes the credit spread term under the model where households face a financial market friction.

5 Optimal Monetary Policy

We assume that a central bank control the nominal interest rate on deposits to maximize the social welfare, following Woodford (2003). The optimal precommitment policy rule for the central bank under the timeless perspective should therefore be obtained by solving the following minimization problem:

$$\min_{\pi, c, \theta, r, \hat{\theta}, \hat{r}, l} E_t \sum_{i=0}^{\infty} \beta^i \left( \lambda_\pi \pi_{t+i}^2 + \lambda_\theta \theta_{t+i}^2 + \lambda_c c_{t+i}^2 \right)$$
subject to the Phillips curve of equation (23), the markup of equation (24), the IS relation of equation (25), and the expressions for the credit market tightness of equation (26), and the consumption of equation (27).

Then, the optimal monetary policy, which is the nominal interest rate, is given by the first order conditions for \( \pi_t, \tilde{\theta}_t, \tilde{c}_t, \tilde{l}_t, \) and \( \tilde{n}_t^D \), respectively as:

\[
\lambda \pi_t \pi_t + \varphi_{1t} - \varphi_{1t-1} - \beta^{-1} \sigma^{-1} \varphi_{2t-1} = 0, \tag{29}
\]

\[
\lambda \varphi_{1t} - \delta(1 - \alpha) \frac{\kappa \varphi_{1t} \rho_{\varphi_{1t-1}}}{\varphi_{1t} - \rho_{\varphi_{1t-1}}} + \varphi_{3t} = 0, \tag{30}
\]

\[
\lambda \varphi_{2t} - \frac{\delta \rho_{\varphi_{1t}}}{Z} (\varphi_{1t-1} - \beta \varphi_{1t}) + \varphi_{2t} - \beta^{-1} \varphi_{2t-1} + \varphi_{4t} = 0, \tag{31}
\]

\[
- \frac{1}{\alpha} \varphi_{3t} + \beta \rho_{\varphi_{1t}} E_t \varphi_{3t+1} + \frac{L \varphi_{4t}}{C} + \varphi_{4t} - \frac{L \varphi_{4t}}{C} E_t \varphi_{4t+1} = 0, \tag{32}
\]

\[
\varphi_{2t} = 0, \tag{33}
\]

where \( \varphi_{1t}, \varphi_{2t}, \varphi_{3t}, \) and \( \varphi_{4t} \) are Lagrangian multipliers for the Phillips curve of the equation (23), the IS relation of the equation (25), and the expressions for the credit market tightness of the equation (26), and the consumption of the equation (27), respectively.

6 Optimal Macroprudential Policy

6.1 Intervention for Nash Bargaining

We introduce a macroprudential policy that intervenes in the setting of the loan interest rate between a firm and a bank through Nash bargaining. The monetary authority control the parameter \( b \) of Nash bargaining as

\[
\max_b \int_t^{b_t} J_t^{1-b_t} dt,
\]

where \( b_t \) is the policy variable of the monetary authority. In reality, the monetary authority controls the degree of competition in the loan market by changing a financial regulations on banks’ competition. In this case, the retail price markup term \( \tilde{\mu}_t \) in the equation (24) changes as
\[ Z_t = -(1 - \alpha) \frac{\kappa \nu}{\alpha \rho L} \left( \hat{\theta}_t - \beta \rho_u E_t \hat{\theta}_{t+1} \right) \]

\[ - \beta \delta_2 \sigma (E_t \hat{c}_{t+1} - \hat{c}_t) \]

\[ - \frac{b}{(1 - b)^2} \frac{\kappa \nu}{\rho L} \left( \hat{b}_t - \beta \rho_u E_t \hat{b}_{t+1} \right). \]

The welfare function and other parts of the model, however, do not change. Then, the optimal policy measure for financial stability is given by

\[ \varphi_{1t} - \rho \varphi_{1t-1} = 0. \]

Accompanied with the optimal monetary policy, under the optimal macroprudential policy, the inflation rate is fixed to zero, and other variables are also zero against the cost-push shock. This is because financial stability leads to price stability via the cost channel. This case shows that the macroprudential policy for financial stability can hold a close relation with price stability and ultimately with the monetary policy.

6.2 Intervention for Credit Separation

Another way to intervene in the credit market could be limiting or controlling the credit separation rate \( \rho \).\(^7\) In this macroprudential policy, the monetary authority controls the total volume of credit. If the change in \( \rho \) affects no other exogenous parameters, it can be shown in our model that the utility is maximized by always setting \( \rho \) to zero. In the real economy, however, constraining natural separation of credit between banks and firms result in a deterioration of productivity.\(^8\) To allow the policy makers to control the separation rate \( \rho_t \), we introduce the following phenomenological relation between the average productivity of wholesale firms \( Z_t \) and the separation rate \( \rho_t \):

\[ Z_t = f(\rho_t), \]

where \( f \) is a monotonically-increasing concave function. We then assume that the expansion of the above relation up to the second order from a steady-state value can be expressed as

\(^7\)We can also make the credit vacancies \( \kappa \) or the matching parameter \( \chi \) as policy variables.

\(^8\)A similar feature for the separation between workers and firms is endogenously captured by the matching model by Mortensen and Pissarides (1994).
\[ Z \left( \hat{z}_t + \frac{1}{2} \hat{z}_t^2 \right) = \bar{p} \left[ f_1 \hat{\rho}_t + \frac{1}{2} (f_1 + f_2 \bar{p}) \hat{\rho}_t^2 \right] , \]  

(34)

where the first and the second derivative of the function \( f \) under the efficient steady-state equilibrium satisfy \( f_1 > 0 \) and \( f_2 \leq 0 \), respectively.

In addition to the equation (17), the efficient steady-state condition becomes,

\[(1 - \bar{p})f_1 = \delta_2 , \]

(35)

where \( \bar{p} \) can be nonzero. In this case, the welfare function becomes

\[
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = -\frac{1}{2} \sum_{i=0}^{\infty} \beta^i \left( \lambda_\pi \pi_{t+i}^2 + \lambda_\theta \theta_{t+i}^2 + \lambda_c \hat{c}_{t+i}^2 + \lambda_\rho \hat{\rho}_{t+i}^2 \right) + \sum_{i=0}^{\infty} \beta^i \psi_\rho \hat{\rho}_{t+i} \left( \hat{t}_{t+i} - \hat{t}_{t+i-1} \right) + t.i.p.,
\]

(36)

where \( \lambda_\rho \equiv u_c \bar{L} \bar{p}^2 \left| f_2 \right| \) and \( \psi_\rho \equiv u_c \bar{L} f_1 \). See the appendix for the details of the calculation.

The implication of this equation is clear. The fact that the last term is linear in \( \hat{\rho} \) suggests that, when the number of credit increases, the society is better off by setting the separation rate higher than the efficient equilibrium value and so by reducing credit. The second-order term \( \lambda_\rho \hat{\rho}_{t+i}^2 \) is then the cost incurred by excessive control of \( \hat{\rho} \) from the concavity of the function \( f \). When the probability of failing to receive an update on the credit line \( \rho \) increases, the relative weight for the terms of the separation rate increase. This is because increase of \( \rho \) raise the cost of holding the credit.

The time-variation in the separation rate modifies the relation between the credit tightness and the number of credit as

\[ \hat{\theta}_t = \frac{1}{\alpha \bar{p}} \left[ \hat{t}_t - \rho_u \hat{t}_{t-1} + \bar{p} \left( 1 - \frac{\bar{p} \bar{L}}{\bar{p}} \right) \hat{\rho}_t \right] . \]

(37)

In addition, the markup equation is modified as

\[
Z \hat{\mu}_t = -\left( 1 - \alpha \right) \frac{k^T}{\alpha \bar{p} \bar{L}} \left( \hat{\theta}_t - \beta \rho_u E_t \hat{\theta}_{t+1} \right) + \beta \delta_2 \sigma \left( E_t \hat{\theta}_{t+1} - \hat{\theta}_t \right) + \delta_2 \frac{\bar{p}}{1 - \bar{p}} \left( \hat{\rho}_t - \beta E_t \hat{\rho}_{t+1} \right) .
\]

(38)
On the other hand, the efficient steady-state condition (35) ensures that the equation (27) between consumption and credit is unchanged up to the first order.

The optimal policy is obtained by maximizing the above utility subject to the Phillips curve of the equation (23), the modified markup of the equation (38), the IS relation of the equation (25), and the expressions for the credit market tightness of the equation (37), and the consumption of the equation (27). This maximization replaces one of the first order conditions (32) by

$$-\psi_0(\hat{\rho}_t - \beta E_t \hat{\rho}_{t+1}) - \frac{1}{\alpha \rho} \varphi_{3t} + \frac{\beta \rho_u}{\alpha \rho} E_t \varphi_{3t+1} + \frac{L_2 \beta}{C} \varphi_{4t} - \frac{L_2 \beta}{C} E_t \varphi_{4t+1} = 0. \quad (39)$$

In addition, the following first order condition for $\varphi_{3t}$ is obtained:

$$\lambda \varphi_{3t} - \psi_0(\hat{\lambda}_t - \hat{\lambda}_{t-1}) + \frac{\delta}{Z} \delta_2 \bar{p} \left( \varphi_{1t} - \varphi_{1t-1} \right) - \frac{\rho_u}{\alpha (1 - \bar{p})} \varphi_{3t} = 0, \quad (40)$$

or by using the equations (29) and (33),

$$\varphi_{3t} = \frac{\alpha \bar{p}}{\rho_u} u_c E \left[ \bar{p} (1 - \bar{p}) |f_2| \hat{\rho}_t - \delta_2 \left( \varepsilon \pi_t + \hat{\lambda}_t - \hat{\lambda}_{t-1} \right) \right]. \quad (41)$$

The optimal macroprudential policy adjusts the separation rate by taking account of the trade-off among the separation rate, credit market tightness, consumption, and the inflation rate, while all of the separation rate, credit market tightness, and consumption are closely related to the amount of credit $\hat{\lambda}_t$ by the equations (27) and (37). In fact, we can explicitly derive the following macroprudential policy by substituting the equations (31) and (41) into the equation (39) to eliminate $\varphi_{3t}$ and $\varphi_{4t}$:

$$A_1 \hat{\rho}_t - \beta A_2 E_t \hat{\rho}_{t+1} = A_3 \left( \varepsilon \pi_t + \hat{\lambda}_t - \hat{\lambda}_{t-1} \right) - \beta \delta_2 A_4 \left( \varepsilon E_t \pi_{t+1} + E_t \hat{\lambda}_{t+1} - \hat{\lambda}_t \right), \quad (42)$$

where

$$A_1 \equiv \frac{\bar{p}}{1 - \bar{p}} \delta_2 + \frac{\bar{p}(1 - \bar{p}) |f_2|}{\rho_u},$$

$$A_2 \equiv \frac{\bar{p}}{1 - \bar{p}} \delta_2 + \bar{p}(1 - \bar{p}) |f_2|,$$

$$A_3 \equiv \frac{L_2 \beta \sigma}{C} + \frac{1}{\rho_u},$$

$$A_4 \equiv \frac{L_2 \beta \sigma}{C} + 1.$$
Note that the equation (27) is used to eliminate $\hat{\gamma}_t$. The form of the equation (42) clearly suggests that the optimal choice of the separation rate is determined by the inflation rate and the increase in the credit $\varepsilon \pi_t + \hat{\kappa} - \hat{\kappa}_{t-1}$. The monetary authority should pay attention to the inflation in addition to the credit since financial market and real economy are tightly connected. Thus, for both the monetary authority and the central bank, it is essential to internalize another policy each other.

7 Concluding Remarks

We introduce the search and matching type of friction into the loan market in a standard New Keynesian model. In this model, the second order approximation of social welfare includes the term relating to credit, such as credit market tightness, the volume of credit, and a loan separation rate, in addition to the inflation rate and the output gap. This is a new finding in a field of the optimal policy. The outcome of the optimal policy changes in accordance with the type of macroprudential policy for financial stability.

For the future research, the following points could be of interest. The model considered in this paper is restricted to the case where the central bank and monetary authority coordinate their policy choices so as to maximize social welfare. An alternative assumption would be that two policy makers set their respective policies in a non-cooperative way. Moreover, we can assume a situation where the macroprudential policy can have impact on disturbances, even though the monetary policy cannot affect them. They can be disturbances from credit spreads on the policy interest rate. Another issue is a question for what kinds of policies are simple and implementable to replicate the optimal policy measure for financial stability, is as in the case with the Taylor rule in the optimal monetary policy analysis. In such an analysis, it would be interesting to quantitatively evaluate priority among stabilization of credit, the inflation rate, and the output gap.

Appendix

A Policy Objective Function with Productivity Shock

The models in the main text do not consider the effect of the productivity shock $Z_t$. This is because, even if $Z_t$ is taken into account as a shock, the mathematical forms of the model would remain the same by taking the difference from an efficient stochastic state equilibrium. In this subsection, we show that the productivity shock alters neither the policy objective function nor any of the linearized structural equations.

When we have a stochastic exogenous productivity $Z_t$, the second order expansion of the household’s utility function around the efficient steady-state equilibrium becomes

$$\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = -\frac{1}{2} \sum_{i=0}^{\infty} \beta^i \left( \lambda_{\pi} \pi_{t+i}^2 + \lambda_{\theta} \theta_{t+i}^2 + \lambda_c c_{t+i}^2 \right)$$

$$+ u_c Zt \sum_{i=0}^{\infty} \beta^i \left( \tilde{z}_{t+i} + \frac{1}{2} \tilde{z}_{t+i}^2 \right) + u_c Zt \sum_{i=0}^{\infty} \beta^i \tilde{z}_{t+i} \hat{l}_{t+i} + t.i.p..$$

Here, although the term

$$u_c Zt \sum_{i=0}^{\infty} \beta^i \left( \tilde{z}_{t+i} + \frac{1}{2} \tilde{z}_{t+i}^2 \right)$$

is clearly t.i.p., the cross term between $\tilde{z}_{t+i}$ and $\hat{l}_{t+i}$ seems relevant. In order to eliminate this term, we consider the log-linearized deviation from the dynamics of efficient stochastic state. This efficient stochastic state is obtained by imposing the Hosios condition $b = 1 - \alpha$ and no price markup $\pi = 1$, although allowing the productivity shock $Z_t$ to move. We write the log-linearized value of a variable $X_t$ at the efficient stochastic state as $x^e_t$ and the deviation from the efficient stochastic state as $\tilde{x}_t \equiv \tilde{x}_t - x^e_t$. At the efficient stochastic state, the consumption up to the first order is

$$c^e_t = \frac{T}{C} (Z \tilde{z}_t - \beta \delta_{2t} l^e_t + \delta_{2t} l^e_{t-1}) .$$

On the other hand, at the efficient stochastic equilibrium, the Euler equation (2) becomes

$$c^e_t = E_t c^e_{t+1} - \frac{1}{\sigma} r^e_t ,$$

where $r^e_t$ is the real interest rate. By substituting the equation (43) into this equation, we obtain
\[
\hat{z}_t = E_t \hat{z}_{t+1} + \frac{\delta_2}{Z} (-\beta E_t r_{t+1}^e + l_t^e + \beta l_{t+1}^e - l_{t-1}^e) - \frac{C}{\sigma Z \bar{L}} r_t^e.
\] (44)

The policy objective function can be divided as

\[
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = A_t + B_t + t.i.p.,
\] (45)

where

\[
A_t = u_c Z L \sum_{i=0}^{\infty} \beta^i \hat{z}_{t+i} \hat{l}_{t+i} - \sigma u_c Z C \delta_2 \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left( \hat{z}_{t+i} \hat{l}_{t+i-1} - \beta \hat{z}_{t+i+1} \hat{l}_{t+i} \right)
\]

is the collection of the terms that include \( \hat{z}_t \), and

\[
B_t = -\frac{1}{2} \lambda \pi \sum_{i=0}^{\infty} \beta^i \pi_{t+i} - u_c \kappa \frac{1 + \alpha}{2} \sum_{i=0}^{\infty} \beta^i \theta_{t+i}^2 - \frac{1}{2} \sigma u_c C \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \hat{l}_{t+i} + \hat{l}_{t+i-1} \right)^2
\]

represents the other terms. By using the equation (44) only for the last term in \( A_t \),

\[
A_t = u_c Z L \sum_{i=0}^{\infty} \beta^i \hat{z}_{t+i} \hat{l}_{t+i} - \sigma u_c Z C \delta_2 \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left( \hat{z}_{t+i} \hat{l}_{t+i-1} - \beta \hat{z}_{t+i+1} \hat{l}_{t+i} \right)
\]

\[
+ \beta \sigma u_c Z C \delta_2 \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left[ \frac{\delta_2}{Z} (-\beta l_{t+i+1}^e + l_{t+i}^e + \beta l_{t+i}^e - l_{t+i-1}^e) - \frac{C}{\sigma Z \bar{L}} r_{t+i}^e \right] \hat{l}_{t+i}
\]

\[
= u_c Z L \sum_{i=0}^{\infty} \beta^i \hat{z}_{t+i} \hat{l}_{t+i} + t.i.p.
\]

\[
+ \beta \sigma u_c Z C \delta_2 \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i \left[ \frac{\delta_2}{Z} (-\beta l_{t+i+1}^e + l_{t+i}^e + \beta l_{t+i}^e - l_{t+i-1}^e) - \frac{C}{\sigma Z \bar{L}} r_{t+i}^e \right] \hat{l}_{t+i}.
\]

On the other hand, the equation (14) implies that, at the efficient stochastic equilibrium, we have

\[
Z \hat{z}_t = (1 - \alpha) \frac{\kappa \bar{V}}{\alpha P L} (\theta_t^e - \beta \rho \phi_t^e) + \beta \delta_2 r_t^e.
\]

By substituting this, \( A_t \) can be further simplified as
\[ A_t = u_c(1 - \alpha) \frac{\kappa_p}{\alpha \rho} \sum_{i=0}^{\infty} \beta^i (\theta_{t+i}^e - \beta \mu_{t+i+1} \widehat{l}_{t+i}) \]

\[ + \beta \sigma u_c \bar{C} \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i+1}^e + l_{t+i}^e + \beta l_{t+i}^e - l_{t+i-1}^e) \widehat{l}_{t+i} + t.i.p. \]

\[ = u_c(1 - \alpha) \frac{\kappa_p}{\alpha \rho} \sum_{i=0}^{\infty} \beta^i \left( \mu_{t+i} + \mu_{t+i}^e \right) \]

\[ + u_c(1 - \alpha) \frac{\kappa_p}{\alpha \rho} \sum_{i=0}^{\infty} \beta^i \mu_{t+i}^e \widehat{l}_{t+i} \]

\[ + \beta \sigma u_c \bar{C} \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i+1}^e + l_{t+i}^e + \beta l_{t+i}^e - l_{t+i-1}^e) \widehat{l}_{t+i} + t.i.p., \]

where \( \widehat{l}_t = \frac{1}{\alpha \rho} (l_t - \beta l_{t-1}) \) is used. The two terms in the first summation on the right-hand side are again t.i.p., and the last summation can be rewritten as

\[ \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i+1}^e + l_{t+i}^e) \widehat{l}_{t+i} + \sum_{i=0}^{\infty} \beta^i (\beta l_{t+i}^e - l_{t+i-1}^e) \widehat{l}_{t+i} \]

\[ = \beta^{-1} \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i}^e + l_{t+i-1}^e) \widehat{l}_{t+i-1} - \beta^{-1} (-\beta l_{t}^e + l_{t-1}^e) \widehat{l}_{t-1} + \sum_{i=0}^{\infty} \beta^i (\beta l_{t+i}^e - l_{t+i-1}^e) \widehat{l}_{t+i} \]

\[ = \beta^{-1} \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i}^e + l_{t+i-1}^e) (\widehat{l}_{t+i} + \widehat{l}_{t+i-1}) + t.i.p.. \]

We thus obtain

\[ A_t = \beta \sigma u_c \bar{C} \left( \frac{L}{C} \right)^2 \sum_{i=0}^{\infty} \beta^i (-\beta l_{t+i}^e + l_{t+i-1}^e) \left( \widehat{l}_{t+i} + \widehat{l}_{t+i-1} \right) \]

\[ + u_c(1 - \rho) \frac{\kappa_p}{\alpha \rho} \sum_{i=0}^{\infty} \beta^i \mu_{t+i}^e \widehat{l}_{t+i} + t.i.p.. \]

This expression for \( A_t \) is substituted into the policy objective function of equation (45), yielding
\[
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = \beta \sigma u_c C \left( \frac{T}{C} \delta_2 \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta l_{t+i} + l_{t+i-1}^e \right) \left( -\beta \tilde{h}_{t+i} + \tilde{l}_{t+i-1} \right) \\
+ u_c (1 - \alpha) \kappa \bar{v} \sum_{i=0}^{\infty} \beta^i \theta_{t+i}^e \tilde{t}_{t+i} \\
- \frac{1}{2} \lambda \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2 - u_c \kappa \bar{v} \frac{1}{2} \sum_{i=0}^{\infty} \beta^i \tilde{h}_{t+i}^2 \\
- \frac{1}{2} \sigma u_c C \left( \frac{T}{C} \delta_2 \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \tilde{h}_{t+i} + \tilde{l}_{t+i-1} \right)^2 + t.i.p. \\
= - \frac{1}{2} \lambda \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2 \\
- \frac{1}{2} \beta \sigma u_c C \left( \frac{T}{C} \delta_2 \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \tilde{h}_{t+i} + \tilde{l}_{t+i-1} - (-\beta l_{t+i} + l_{t+i-1}) \right)^2 \\
- u_c \kappa \bar{v} \frac{1}{2} \sum_{i=0}^{\infty} \beta^i \left( \tilde{h}_{t+i} + \theta_{t+i}^e \right)^2 + t.i.p. \\
= - \frac{1}{2} \lambda \sum_{i=0}^{\infty} \beta^i \pi_{t+i}^2 - \frac{1}{2} \beta \sigma u_c C \left( \frac{T}{C} \delta_2 \right)^2 \sum_{i=0}^{\infty} \beta^i \left( -\beta \tilde{h}_{t+i} + \tilde{l}_{t+i-1} \right)^2 \\
- u_c \kappa \bar{v} \frac{1}{2} \sum_{i=0}^{\infty} \beta^i \tilde{h}_{t+i}^2 + t.i.p.,
\]

which can be simplified as:

\[
\sum_{i=0}^{\infty} \beta^i u(C_{t+i}) = - \sum_{i=0}^{\infty} \beta^i \frac{1}{2} \left( \lambda \pi_{t+i}^2 + \lambda \theta_{t+i}^2 + \lambda c_{t+i}^2 \right).
\]

We therefore confirm that the form of the utility-based policy objective function remains the same even when we introduce the productivity shock. In addition, we can easily see that all the relevant structural equations (23, 24, 25, 26, and 27) can be written identically if we replace $\hat{x}$ by $\tilde{x}$ for all the variables $X_t$.

**B Policy Objective Function with Time-Dependent Separation Rate**

In this section, we show the derivation of the equations (35) and (36).

The efficient steady-state condition is obtained by the following maximization problem:
\[ \max_{C, L, u, \theta, \rho} \mathbb{E}_t \sum_{i=0}^{\infty} \beta^i \left[ C^{1-\sigma}_{t+i} + \lambda_{t+i} [f(\rho_{t+i}) L_{t+i} - a L_{t+i} - \kappa \theta_{t+i} u_{t+i} - C_{t+i}] + \psi_{t+i}[(1 - \rho_{t+i}) L_{t+i-1} + \chi \theta_{t+i}^\alpha u_{t+i} - L_{t+i}] + s_{t+i} [u_{t+i} - 1 + (1 - \rho_{t+i}) L_{t+i-1}] \right]. \]

By taking the first-order conditions for the five variables and rearranging the equations, we obtain

\[ f(\rho_t) - a - \frac{\kappa \theta_t^{1-\alpha}}{\alpha \chi} = -\beta \mathbb{E}_t \frac{\lambda_{t+1}}{\lambda_t} (1 - \rho_{t+1}) \left( \frac{\kappa \theta_{t+1}^{1-\alpha}}{\alpha \chi} + \frac{\alpha - 1}{\alpha} \kappa \theta_{t+1} \right), \]

and

\[ f'(\rho_t) \frac{L_t}{L_{t-1}} = \frac{\kappa \theta_t^{1-\alpha}}{\alpha \chi} + \frac{\alpha - 1}{\alpha} \kappa \theta_t. \]

At the efficient steady-state equilibrium, the former condition becomes identical to the equation (17), while the latter can be rearranged to the condition (35).

We note that the latter equation, when linearized around the efficient steady-state equilibrium, is written as

\[ f_2 \tilde{\rho}_t + f_1 (\hat{L}_t - \hat{L}_{t-1}) = \frac{1 - \alpha}{\alpha} \frac{\kappa \theta_t^{1-\alpha}}{\chi} \left( 1 - \chi \tilde{\theta}^\alpha \right), \]

and could be obtained from the optimal policy in the main text, if there were no inflation.

This point can be easily confirmed by substituting the equation (30) into the equation (40) to eliminate \( \varphi_{3t} \) and by remembering that \( \varphi_{1t} \) is zero without inflation from the equation (29).

As for the second-order expansion of the utility, both the time-dependence of the separation rate \( \rho_t \) and the productivity \( Z_t \) make the calculation slightly complicated, although the basic procedure of the derivation is straightforward. For example, the productivity enters the expansion of consumption, and the equation corresponding to the equation (18) becomes:

\[ \hat{c}_t + \frac{1}{2} \tilde{\sigma}_t^2 = \frac{Z T}{C} \left( \hat{z}_t + \frac{1}{2} \tilde{z}_t^2 + \tilde{z}_t \hat{l}_t - \hat{q}_t \right) + \frac{(Z - a) T}{C} \left( \hat{l}_t + \frac{1}{2} \tilde{l}_t^2 \right) - \frac{\kappa \tilde{\theta}}{C} \left( \hat{v}_t + \frac{1}{2} \tilde{v}_t^2 \right). \]

On the other hand, the expansion of the credit vacancy (19) is modified by the time-dependence of the separation rate as:
\[ \tilde{v}_t + \frac{1}{2} \tilde{v}^2_t = \left( \hat{\theta}_t + \frac{1}{2} \hat{\theta}^2_t \right) - \eta \left( \hat{\theta}_{t-1} + \frac{1}{2} \hat{\theta}^2_{t-1} \right) - \eta \hat{\theta}_t \hat{\theta}_{t-1} \]
\[ + \frac{\tilde{\nu}_t \tilde{u}}{\nu} \left( \hat{\rho}_t + \frac{1}{2} \hat{\rho}^2_t + \hat{\rho}_t \hat{\rho}_{t-1} + \hat{\rho}_t \hat{\rho}_{t-1} \right). \]

After eliminating the credit market tightness \( \hat{\theta}_t \) by using

\[ L_t = (1 - \rho_t)L_{t-1} + \chi \theta^p_t \nu_t, \]

we obtain the following expansion of the utility:

\[ u(C_t) = u(\bar{C}) + u_c Z \left( \tilde{\zeta}_t + \frac{1}{2} \tilde{\zeta}^2_t + \tilde{\zeta}_t \tilde{\zeta}_t - \tilde{q}_t \right) \]
\[ - u_c \frac{k \kappa}{\alpha} \left( 1 - (1 - \alpha) \frac{\tilde{\nu}_t \tilde{u}}{\nu} \right) \left( \hat{\rho}_t + \frac{1}{2} \hat{\rho}^2_t + \hat{\rho}_t \hat{\rho}_{t-1} \right) \]
\[ + u_c C \left[ \frac{\tilde{\zeta}_t + \delta_1 \tilde{\zeta}_t + \delta_2 \tilde{\zeta}_t - \tilde{q}_t}{\nu} \right]^2 \]
\[ - \frac{1}{2} \sigma u_c C \left( \frac{\tilde{\zeta}_t + \delta_1 \tilde{\zeta}_t + \delta_2 \tilde{\zeta}_t - \tilde{q}_t}{\nu} \right) \left( 1 - (1 - \alpha) \frac{\tilde{\nu}_t \tilde{u}}{\nu} \right) \left( \hat{\rho}_t + \hat{\rho}_t \right)^2. \]

At this stage, by using the equations (34) and (35), we observe that the first-order difference between \( \tilde{\zeta}_t \) and \( \hat{\theta}_t \) is cancelled, and we finally obtain the equation (36).
